

THE ZERO PARADOX

ZP-L: Incomputability Convergence

Version 1.0 | May 2026

v1.0: Initial release. All theorems §I–§VII proved sorry-free in Lean 4. Axiom footprint: [propext, Classical.choice, Quot.sound] throughout.

ZP-L establishes four results connecting the formal axioms of the ZP framework to standard results in ordinal theory and computability. First, Classical.choice appears at the non-constructive diagonal step in each of the four mathematical settings of the ZP framework — topology, information theory, set theory, and computation. Second, Roger’s fixed-point theorem (Kleene’s second recursion theorem) is formalized as a wrapper, formalizing the computational fixed-point structure. Third, the ordinal ϵ_0 is fully characterized as the first fixed point of $\alpha \mapsto \omega^\alpha$ and the limit of the tower $\omega, \omega^\omega, \omega^{\omega^\omega}, \dots$. Fourth, ordinals below ϵ_0 encode into $\mathbb{Z}_2$ via their Cantor normal form, and as the tower stages approach ϵ_0 , their 2-adic encodings converge to $0 = \perp$.

The central result (§VII) is the canonical snap map: $\phi \alpha = \text{if } \alpha < \epsilon_0 \text{ then } c_0 \text{ else } c_1$ simultaneously satisfies all five conditions — monotone, tower-aligned, fixed-point-respecting, snapping at ϵ_0 , and ϵ_0 minimal. All conditions are verified without free hypotheses for this witness. 24 theorems proved, zero sorry, axiom footprint [propext, Classical.choice, Quot.sound] throughout.

Section I: Axiom Footprint Convergence

Non-constructibility appears in four mathematical settings across the ZP framework. Classical.choice is required at each diagonal step in these proofs — a constructive alternative was not found in any of the four settings.

Layer	Formal Language	Expression of non-constructibility
ZPB	Topology	C3: no continuous path $\perp \rightarrow x \neq \perp$
ZPC	Information Theory	L-INF: infinite surprisal at $\perp$
ZPJ/K	Set Theory + Computation	bot_self_mem (AFA); botCode (Kleene)
ZPI	Algorithmic IT	$K(S^{\mathbb{N}} n)/ S^{\mathbb{N}} \rightarrow 1$; K uncomputable

Remark: Why K is Absent from Lean

Kolmogorov complexity K is not computed in Lean in this framework. Its existence as a total function requires Classical.choice — exactly the axiom Nat.Partrec.Code.fixed_point₂ already uses in ZP-K. The AFA/Kleene route reaches the same fixed-point structure via a provable path without requiring K to be explicitly computed.

Axiom footprint evidence — the following ZP-K theorems all carry [propext, Classical.choice, Quot.sound]:

Remark: Why K is Absent from Lean

ZPK.t_comp (T-COMP four-way equivalence)

ZPK.da1_paths_unified

ZPK.isComputationalQuine_undecidable

ZPK.infinite_quine_family

The Classical.choice entry is the computational expression of the diagonal. ZP-L inherits this footprint throughout.

Section II: Roger Fixed-Point Stability

Roger's fixed-point theorem (also known as Kleene's second recursion theorem) states that any computable transformation of a code has a behavioral fixed point: a code c such that running $f(c)$ and running c produce the same partial function. For any computable transformation, at least one fixed-point code exists.

Theorem: roger_fixed_point_stability (ZPL.lean §II)

For any computable $f : \text{Code} \rightarrow \text{Code}$,

$\exists c : \text{Code}, \text{eval } (f\ c) = \text{eval } c$

Proof: wrapper around ZPK.roger_fixed_point_exists.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Note: this is an existential result. The specific code c is not constructively produced; Classical.choice selects it. This is the same non-constructive step that appears across all ZP layers (§I).

Section III: The Ordinal ε_0

The ordinal ε_0 is the smallest fixed point of the map $\alpha \mapsto \omega^\alpha$. It is the supremum of the tower $0, 1, \omega, \omega^\omega, \omega^{\omega^\omega}, \dots$ — each stage is strictly below ε_0 , and ε_0 is not reached by any finite iteration. This section is entirely within Lean scope via Mathlib's ordinal machinery.

Definitions (ZPL.lean §III)

$\text{epsilonZero} : \text{Ordinal} := \text{Ordinal.epsilon } 0 (= \text{nfp } (\omega^\cdot) 0 = \text{veblen } 1\ 0)$

$\text{fundamentalSeq} : \mathbb{N} \rightarrow \text{Ordinal} := \text{fun } n \mapsto (\alpha \mapsto \omega^\alpha)^\wedge[n]\ 0$

Explicit stages:

$\text{fundamentalSeq } 0 = 0$

$\text{fundamentalSeq } 1 = 1$

Definitions (ZPL.lean §III)

$\text{fundamentalSeq } 2 = \omega$

$\text{fundamentalSeq } 3 = \omega^\omega$

$\text{fundamentalSeq } (n+1) = \omega^{(\text{fundamentalSeq } n)}$

Theorem: epsilonZero_fixedPoint

$\omega^{\varepsilon_0} = \varepsilon_0$

Proof: Ordinal.omega0_opow_epsilon 0 (Mathlib).

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: epsilonZero_eq_nfp

$\varepsilon_0 = \text{nfp } (\omega^{\cdot}) 0$

Proof: Ordinal.epsilon_zero_eq_nfp (Mathlib).

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: epsilonZero_eq_iSup

$\varepsilon_0 = \sqcup n : \mathbb{N}, \text{fundamentalSeq } n$

Proof: iSup_iterate_eq_nfp (Mathlib).

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: epsilonZero_tower_lt

$\forall n : \mathbb{N}, \text{fundamentalSeq } n < \varepsilon_0$

Every finite stage of the tower is strictly below ε_0 .

Proof: Ordinal.iterate_omega0_opow_lt_epsilon_zero (Mathlib).

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: epsilonZero_le_fixedPoint

$\forall b : \text{Ordinal}, \omega^b = b \rightarrow \varepsilon_0 \leq b$

ε_0 is the least fixed point of $\omega^{\cdot}$ above 0.

Proof: Ordinal.epsilon_zero_le_of_omega0_opow_le (Mathlib).

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: fundamentalSeq_strictMono

$\forall n : \mathbb{N}, \text{fundamentalSeq } n < \text{fundamentalSeq } (n + 1)$

The tower is strictly monotone.

Proof: by induction; successor step uses `isNormal_opow`.

Lean purity: `[propext, Classical.choice, Quot.sound]`. ✓

Remark R-L.1: Proof-Theoretic Alignment

Gentzen's theorem (1936) establishes that ϵ_0 is the proof-theoretic ordinal of Peano Arithmetic: PA can prove transfinite induction for any ordinal strictly below ϵ_0 , but not for ϵ_0 itself. This is not claimed or proved here.

ZP-L derives ϵ_0 as the snap threshold from ordinal fixed-point structure, independently of proof theory. Both derivations locate the same boundary: the ordinal where ω -tower self-iteration becomes self-limiting. No claim is made that this alignment is more than a structural observation.

Remark R-L.2: Surreal Numbers

Every ordinal is a surreal number (Conway, 1976), so ϵ_0 lives in the surreal number field No . No satisfies the axioms of a real-closed field, and by Tarski's completeness theorem for the theory of real-closed fields, every first-order sentence in the language of ordered fields that holds in $\mathbb{R}$ also holds in No , and vice versa.

ZP-F (The Counterexamples) proves that the Binary Snap — the forced transition from $\perp$ to the first non-null ordinal threshold (ϵ_0 , established in §V–§VII above) — cannot occur in any linearly ordered field. This result applies directly to No considered as a linearly ordered field.

The surreals therefore contain ϵ_0 as an ordinal while simultaneously satisfying the density condition that blocks the Binary Snap in their ordered field structure. Both structures coexist in No : ϵ_0 is present as an ordinal, and the field density that blocks the snap is present in the field structure. The two results apply to different structural aspects of No .

Remark R-L.3: Hyperreals and Łoś's Theorem

The hyperreals ${}^*\mathbb{R} = \mathbb{R}^{\mathbb{N}}/U$ (ultrafilter U on $\mathbb{N}$) satisfy a transfer result: by Łoś's theorem, every first-order sentence true in $\mathbb{R}$ holds in ${}^*\mathbb{R}$. Łoś's theorem applies to the full first-order theory, so any first-order property of $\mathbb{R}$ — including field density — transfers.

Field density transfers: between any two hyperreals there is another. The density condition that blocks the Binary Snap in $\mathbb{R}$ (proved in ZP-F) therefore holds in ${}^*\mathbb{R}$ as well.

The non-standard naturals ${}^*\mathbb{N}$ contain infinite elements, but every infinite $H \in {}^*\mathbb{N}$ has a predecessor $H-1$ in ${}^*\mathbb{N}$. ϵ_0 is a limit ordinal: it has no predecessor and is the supremum of the tower below it. ${}^*\mathbb{N}$ cannot host the Binary Snap not only because of field density, but because its infinite elements are successor-like rather than limit-like. The snap requires genuine limit ordinal structure.

The monad of 0 in ${}^*\mathbb{R}$ — the external set $\{\varepsilon : |\varepsilon| < 1/n \text{ for all standard } n\}$ — is external to the ultrapower. Between any two distinct elements of the monad there is another (their arithmetic mean in ${}^*\mathbb{R}$), so no discrete jump at 0 is possible in ${}^*\mathbb{R}$.

Remark R-L.3: Hyperreals and Łoś's Theorem

Field density is an internal property of the ordered field structure of ${}^*\mathbb{R}$ and transfers by Łoś's theorem. Limit ordinal structure is set-theoretic and is not preserved by the ultrapower construction: ${}^*\mathbb{N}$ contains only successor-like infinite elements, not limit-like ones. The two results — transfer of density, failure of limit-ordinal structure — come from different theorems.

Section IV: Cantor Normal Form Bridge

Every ordinal below ε_0 has a unique Cantor normal form — a finite expression $a_1 \cdot \omega^{e_1} + a_2 \cdot \omega^{e_2} + \dots + a_k \cdot \omega^{e_k}$ with $e_1 > e_2 > \dots > e_k$ and $a_i < \omega$. In Lean: `NONote` (`Mathlib.SetTheory.Ordinal.Notation`). The encoding `cnfToZp2` maps each such ordinal to $\mathbb{Z}_2$ via structural recursion on the Cantor normal form.

Definition: `cnfToZp2` (ZPL.lean §IV)

`cnfToZp2` : `NONote` $\rightarrow$ $\mathbb{Z}_2$

Base: `cnfToZp2`(0) = 0

Recursive: `cnfToZp2`($\omega^e \cdot n + a$) = $2^{(v_2(\text{cnfToZp2}(e)) + 1)} \cdot n + \text{cnfToZp2}(a)$

where v_2 denotes the 2-adic valuation.

Valuation of the n -th tower stage:

`cnfToZp2`(`towerNONote` 0) = 0 (valuation 0)

`cnfToZp2`(`towerNONote` 1) = 2 (valuation 1)

`cnfToZp2`(`towerNONote` 2) = 4 (valuation 2)

`cnfToZp2`(`towerNONote` n) = 2^n (valuation n)

Theorem: `cnfToZp2_tower_valuation`

$\forall n : \mathbb{N}, (\text{cnfToZp2 } (\text{towerNONote } n)).\text{valuation} = n$

The 2-adic valuation of the n -th tower stage encoding equals n .

Proof: by induction; successor step uses `PadicInt.valuation_pow`.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: `cnfToZp2_valuation_unbounded`

$\forall k : \mathbb{N}, \exists \alpha : \text{NONote}, k \leq (\text{cnfToZp2 } \alpha).\text{valuation}$

The 2-adic valuation is unbounded across ordinals below ε_0 .

Proof: `towerNONote` k witnesses the bound.

Theorem: cnfToZp2_valuation_unbounded

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: tower_converges_to_zero

Filter.Tendsto (fun n ↦ cnfToZp2 (towerNONote n)) Filter.atTop (nhds 0)

The tower encodings converge to $0 = \perp$ in $\mathbb{Z}_2$.

Proof: each stage $\text{cnfToZp2}(\text{towerNONote}(n+1)) = 2^{n+1}$ in $\mathbb{Z}_2$, so its 2-adic norm is $\|2\|^{n+1} = (1/2)^{n+1} \rightarrow 0$. Uses Metric.tendsto_atTop and exists_pow_lt_of_lt_one.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Section V: Ordinal Tower Limit and Snap Threshold

This section connects the ordinal tower to the ZPE machine-phase snap. The cofinality theorem shows that the fundamental sequence approaches ε_0 from below. The lower-bound theorem shows that any monotone tower-aligned map must assign c_0 to all pre- ε_0 ordinals. A canonical witness snapping exactly at ε_0 is exhibited.

What this does NOT claim (§V)

Gentzen's theorem: that ε_0 is the proof-theoretic ordinal of PA (not claimed — see Remark R-L.1).

Any statement about formal provability in PA.

That ε_0 is the UNIQUE minimal snap boundary: snap_threshold_is_epsilon_zero shows no ordinal below ε_0 works (for maps satisfying the stated hypotheses), but does not rule out maps that snap at some ordinal strictly above ε_0 .

That the snap threshold result applies to all maps $\text{Ordinal} \rightarrow \text{MachinePhase}$ regardless of the monotonicity and tower-alignment hypotheses.

Theorem: fundamentalSeq_cofinal

$\forall \alpha : \text{Ordinal}, \alpha < \varepsilon_0 \rightarrow \exists n : \mathbb{N}, \alpha < \text{fundamentalSeq } n$

The fundamental sequence is cofinal in ε_0 : for any ordinal below ε_0 , some tower stage exceeds it.

Proof: $\varepsilon_0 = \text{nfp } (\omega^\cdot) 0$ (epsilonZero_eq_nfp), and lt_nfp_iff gives $a < \text{nfp } f b \leftrightarrow \exists n, a < f^n[n] b$.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: snap_threshold_is_epsilon_zero

For any $\phi : \text{Ordinal} \rightarrow \text{MachinePhase}$ satisfying:

(a) hmono: $\forall \alpha \leq \beta, \text{join } (\phi \alpha) (\phi \beta) = \phi \beta$ (order-non-decreasing in the ZPSemilattice sense: $\phi \alpha \leq \phi \beta$)

Theorem: snap_threshold_is_epsilon_zero

(b) h0: $\forall n : \mathbb{N}, \phi(\text{fundamentalSeq } n) = c_0$

we have: $\forall \alpha < \varepsilon_0, \phi \alpha = c_0$

This is a lower bound: no ordinal below ε_0 is a snap point for maps satisfying (a) and (b). "Minimal" not "unique."

Proof: cofinality gives a stage above α ; monotonicity chains $\phi \alpha \leq \phi(\text{stage}) = c_0$; $c_0 = \perp$ forces $\phi \alpha = c_0$.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: c1_epsilon_zero_identification

$\exists \phi : \text{Ordinal} \rightarrow \text{MachinePhase},$

$(\forall n : \mathbb{N}, \phi(\text{fundamentalSeq } n) = c_0) \wedge \phi \varepsilon_0 = c_1$

Witness: $\phi \alpha = \text{if } \alpha < \varepsilon_0 \text{ then } c_0 \text{ else } c_1.$

One specific map sends all tower stages to c_0 and ε_0 to c_1 .

The stronger structural claim — an order-preserving morphism $\text{Ordinal} \rightarrow \text{MachinePhase}$ compatible with the CNF $\rightarrow \mathbb{Z}_2$ encoding — remains outside Lean scope: no type bridge between Ordinal and MachinePhase is defined in this library.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Section VI: Kleene-Ordinal Fixed-Point Bridge

The ordinal fixed-point structure ($\varepsilon_0 = \text{nfp } (\omega^\wedge \cdot) 0, \omega^\wedge \varepsilon_0 = \varepsilon_0$) and the computational fixed-point structure (Kleene's recursion theorem, `roger_fixed_point_stability`) both require `Classical.choice` at their non-constructive step — parallel structure, not a proved isomorphism. The hypothesis `hfp` encodes that ordinal fixed points of $\omega^\wedge \cdot$ map to the snap state c_1 . Under this hypothesis plus monotonicity and tower alignment, ε_0 is the minimal snap threshold.

Theorem: snap_exactly_at_epsilon_zero

For any $\phi : \text{Ordinal} \rightarrow \text{MachinePhase}$ satisfying:

(a) hmono: order-non-decreasing $(\text{join } (\phi \alpha) (\phi \beta) = \phi \beta \text{ for } \alpha \leq \beta)$

(b) h0: every tower stage maps to c_0

(c) hfp: every fixed point of $\omega^\wedge \cdot$ maps to c_1

we have: $\phi \varepsilon_0 = c_1$ AND $\forall \alpha, \phi \alpha = c_1 \rightarrow \varepsilon_0 \leq \alpha$

ε_0 is the minimal snap threshold: ϕ assigns c_1 first at ε_0 .

Theorem: snap_exactly_at_epsilon_zero

Note: "minimal" not "unique." A map satisfying these hypotheses could also assign c_1 to ordinals above ε_0 ; what is ruled out is any snap strictly before ε_0 .

Proof: upper bound from hfp + epsilonZero_fixedPoint; lower bound from snap_threshold_is_epsilon_zero.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: kleene_ordinal_snap_bridge

$\exists \phi : \text{Ordinal} \rightarrow \text{MachinePhase},$

$(\forall n : \mathbb{N}, \phi(\text{fundamentalSeq } n) = c_0) \wedge$

$(\forall \alpha, \omega^\alpha \alpha = \alpha \rightarrow \phi \alpha = c_1) \wedge$

$\phi \varepsilon_0 = c_1 \wedge$

$\forall \alpha, \phi \alpha = c_1 \rightarrow \varepsilon_0 \leq \alpha$

Witness: $\phi \alpha = \text{if } \alpha < \varepsilon_0 \text{ then } c_0 \text{ else } c_1$.

Note: the theorem name refers to the informal §VI conceptual parallel between Kleene recursion fixed points and ordinal fixed points of $\omega^\cdot$. The theorem itself is purely ordinal — no Code or eval appears.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Section VII: Canonical Snap Map — Full Closure

The canonical threshold map $\phi \alpha = \text{if } \alpha < \varepsilon_0 \text{ then } c_0 \text{ else } c_1$ satisfies all three conditions of snap_exactly_at_epsilon_zero (hmono, h0, hfp). For this specific map, the snap identification is unconditional: all five conditions are simultaneously verified without free hypotheses.

Theorem: snap_map_mono

$\forall \alpha \beta : \text{Ordinal}, \alpha \leq \beta \rightarrow$

$\text{join}(\text{if } \alpha < \varepsilon_0 \text{ then } c_0 \text{ else } c_1)$

$(\text{if } \beta < \varepsilon_0 \text{ then } c_0 \text{ else } c_1) =$

$\text{if } \beta < \varepsilon_0 \text{ then } c_0 \text{ else } c_1$

The canonical map is order-non-decreasing.

Proof: four cases (α/β vs ε_0). The case $\alpha \geq \varepsilon_0$ with $\beta < \varepsilon_0$ is impossible by $\alpha \leq \beta$. Each live case closes by rfl from the MachinePhase join definition.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: epsilon_zero_snap_canonical

$\exists \phi : \text{Ordinal} \rightarrow \text{MachinePhase},$

$(\forall \alpha \beta, \alpha \leq \beta \rightarrow \text{join}(\phi \alpha)(\phi \beta) = \phi \beta) \wedge [\text{hmono}]$

$(\forall n : \mathbb{N}, \phi(\text{fundamentalSeq } n) = c_0) \wedge [\text{h0}]$

$(\forall \alpha, \omega^\alpha \alpha = \alpha \rightarrow \phi \alpha = c_1) \wedge [\text{hfp}]$

$\phi \varepsilon_0 = c_1 \wedge [\text{snap}]$

$\forall \alpha, \phi \alpha = c_1 \rightarrow \varepsilon_0 \leq \alpha$ [minimality]

All five conditions verified for the explicit witness $\phi \alpha = \text{if } \alpha < \varepsilon_0 \text{ then } c_0 \text{ else } c_1$, with no free hypotheses.

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Theorem: snap_zp2_correspondence

Four independent facts about the same tower sequence:

(i) $\forall n : \mathbb{N}, \text{fundamentalSeq } n < \varepsilon_0$

(ii) $\forall n : \mathbb{N}, \phi(\text{fundamentalSeq } n) = c_0$ where ϕ is the canonical map

(iii) $\text{Filter.Tendsto}(\text{fun } n \mapsto \text{cnfToZp2}(\text{towerNONote } n)) \text{ Filter.atTop (nhds } 0)$

(iv) $\phi \varepsilon_0 = c_1$

The same tower sequence witnesses both the ordinal approach to ε_0 and the 2-adic approach to 0. The full structural identification ($\varepsilon_0 \leftrightarrow \perp$ via a type bridge) remains outside Lean scope — see §V.

Proof: $\langle \text{epsilonZero_tower_lt}, \text{fun } n \mapsto \text{if_pos } \dots, \text{tower_converges_to_zero}, \text{if_neg } (\text{lt_irrefl } \varepsilon_0) \rangle$

Lean purity: [propext, Classical.choice, Quot.sound]. ✓

Remaining Formal Gap

The Remaining Gap

The identification of ZPE's MachinePhase element c_1 with the ordinal ε_0 via a formal type bridge remains outside Lean scope.

What is proved: a canonical map $\text{Ordinal} \rightarrow \text{MachinePhase}$ assigns c_1 exactly at ε_0 and nowhere earlier. What is not proved: a canonical ZPSemilattice morphism $\text{MachinePhase} \rightarrow \mathbb{Z}_2$ that would connect ZPE's $\perp = c_0$ to ZPB's $\perp = 0$ formally.

Such a bridge would require:

The Remaining Gap

(1) $\text{snapEmbed} : \text{MachinePhase} \rightarrow \mathbb{Z}_2$ mapping $c_0 \mapsto 0, c_1 \mapsto 1$

(2) proof that snapEmbed is join-preserving

(3) a bridge theorem deriving hfp from $\text{tower_converges_to_zero}$ via snapEmbed

This would make hfp a theorem rather than a hypothesis in $\text{snap_exactly_at_epsilon_zero}$. The canonical witness ($\text{epsilon_zero_snap_canonical}$) satisfies all five conditions without this bridge; the bridge would close the gap between the two formal instances of $\perp$ across ZPE and ZPB.

Axiom Purity

All 23 theorems carry axiom footprint: [propext, Classical.choice, Quot.sound].

These are standard Mathlib infrastructure axioms (ordinal theory, p-adic analysis, computability). They are not ZP-L commitments.

Classical.choice is load-bearing: it is the formal non-constructivity appearing at the diagonal step in each ZP layer (§I). Its presence is expected and documented, not incidental.

Zero sorry in ZPL.lean. Verified: lake build, May 2026.
